ABSTRACT

Objective: The objective is to assess the prevalence of caries in children with perinatal HIV infection.

Methods: Oral examination was performed on Children aged 2-12 years with perinatal HIV infection who stayed at ‘Calvary Chapel home of hope for special children’ in Bangalore, to assess dmft/DMFT.

Results: Prevalence of tooth decay in primary teeth (dmft) for the age group 2-6 years was 57.15%, for age group 7-12 years was 20.0%. Prevalence of tooth decay in permanent teeth (DMFT), for the age group 7-8 years was 16.60%, for age group 10-12 years was 21.42%. Of the 27 children examined 59.25% were caries free, in which 40.0% were male children and 70.58% were female children.

Conclusions: Based on these results we can conclude that oral hygiene can be maintained with a favorable dental behavior

Keywords: Caries, Diet, Dental Health

INTRODUCTION

In worldwide it is estimated that there are 2.3 million HIV positive children from 0 to 14 years infected by mothers (1). In children, the quality of life related to health should be considered differently from adults (2). The high prevalence of HIV infection reinforces the need of dentists and his staff to update the prevention and treatment of diseases and the promotion and maintenance oral health of individuals with HIV/ AIDS (2).

Prior to 1992, information about dental caries in HIV-infected children was very limited (3). Of the published articles on the oral manifestation of AIDS, virtually all addressed this issue only in an adult population. In one of these studies, HIV-infected adultshad a lower prevalence of dental caries than a comparison group of healthy adults from the same region of Zaire (4). Another adult study found that there was an association between dental caries and Capnocytophagakeraatitis (5). A Russian study found a high incidence of dental caries in symptom free HIV-infected adults (6). It was not until the late 1980s that investigators started to turn attention to the oral manifestations of HIV-infected children, but none of those earlier writings reported on the disease of dental caries (7-9). Between 1992 and 1996 there were three published cross-sectional studies of dental caries in the primary teeth of HIV-infected children (10-12). These studies showed that there was a higher prevalence of dental caries (including ECC) in the primary dentition of HIV-infected children as compared to healthy children. However, in a 1996 case control study of caries prevalence in a group of children aged 1.5 to 12 years, Teles, G et al. reported a lower dmft for
HIV-infected children as compared to healthy children, as well as a higher DMFT (13). Vieira, et al., reported that HIV-infected children (aged 2-12 years), who were more immunologically affected (CD4/CD8 < 0.5 ratio) showed a greater DMFT/dmf index than HIV-infected children who were immunocompetent (14).

Standard antibody testing is now available to determine a person’s HIV status at an early age. However because of the expense of the complex technology, health workers in developing countries – where 95% of the world’s paediatric AIDS cases are found – must rely on early clinical manifestations of HIV infection (15). Moreover, the use of disease markers prevalent in adult HIV infection is not necessarily effective in the paediatric AIDS population. CD4 lymphocytes, for example, where HIV primarily resides and multiplies, decline with the progression of HIV disease in infected adults; in children, however, a CD4 count alone is not as reliable a marker of progressive disease because children tend to have higher and less consistent CD4 levels than do adults (16,17).

In the light of the above factors the aim of this study was to assess the prevalence of dental caries in children with perinatal HIV infection.

**HYPOTHESIS**

**Null Hypothesis (H₀):** The prevalence of dental caries in children with perinatal HIV infection is not different from that of normal children residing in the same region.

**Alternative Hypothesis (H₁):** The prevalence of dental caries in children with perinatal HIV infection is higher than that of normal children residing in the same region.

**MATERIALS AND METHODS**

**Source of data**

Children aged 2-12 years staying at Calvary Chapel home of hope for special children in Bangalore, with perinatal HIV infection were chosen as subjects.

**Method of data collection**

27 subjects with perinatal HIV infection fulfilled the criteria and were included in the study. The participation of the subjects in the study was voluntary, and a written informed consent was obtained at the beginning of the study.

**Inclusion criteria**

1. Children with perinatal HIV infection
2. Children stayed at ‘Calvary Chapel home of hope for special children’
3. Age group: 2-12 years

**Exclusion criteria**

1. Children with any oral lesions
2. Children on medications other than anti viral therapy
3. Chronic inflammatory diseases like Rheumatoid arthritis which require Medication

**TRAINING AND CALIBRATION**

The investigator was trained in the department of Pediatric dentistry, Government Dental College and Research Institute Bangalore, on 10 subjects. Calibration was done on 10 subjects, who were examined twice using diagnostic criteria on the same day with a time interval of one hour between the two examinations, and then the results were compared to diagnostic variability. Agreement for assessment was 90 percent.

**EXAMINATION**

The examination procedure was carried out at the calvary chapel home of hope for special children under natural light by single investigator. The children were made to sit on a cement bench. The oral examination was performed according to World Health Organization guidelines for oral health surveys. The diagnosis of developmental enamel defects was done according to the modified developmental defects of enamel index. Examination was carried out using 27 mouth mirrors and 27 periodontal probes. Examination of children was undertaken to determine caries prevalence using dmft/DMFT, and developmental enamel defects. The examiner started with the
upper left central incisor and continued distally through the second molar in the same quadrant. The same sequence was followed for the upper right, lower left, and lower right quadrants. Tooth surfaces were examined in the following order: lingual, labial, mesial, and distal for anterior teeth, and occlusal, lingual, buccal, mesial, and distal for posterior teeth. (Image 1)

Guardians were interviewed to obtain information on their children’s dental health behaviors such as tooth-brushing, diet, fluoride; oral medication and dental attendance were explored.

Data collected was used to estimate the mean number of teeth, the number of teeth with carious lesions, number of missing/extracted teeth and number of teeth with restorations. Caries was defined by presence of decayed or filled teeth, and was categorized as present or absent.

As the subjects stayed in the special home for children with HIV infection, a suitable control group was not found. Hence the prevalence of dental caries (dmft and DMFT) in children with perinatal HIV infection was compared with the prevalence of dental caries in normal children residing in the same city, which was found in a large study conducted in Bangalore city (18).

**RESULTS**

The study population was composed of 27 children, there were 62% (n=17) female children and 38% (n=10) male children. 27 children ranged in age from two to twelve (2-12) years, with a mean age of 8.407 years. Developmental enamel defects nor the discrepancies in the average number of teeth for their age were found. All the twenty seven children brushed their teeth twice daily with a tooth brush and tooth paste to clean their teeth.

**Caries**

Prevalence of tooth decay in primary teeth (dmft) for the age group 2-6 years was 57.15%, for age group 7-12 years was 20.0%. 50.0% of male children were free of decay in the primary teeth, however 82.36% of female children were free of decay in the primary teeth (Table 1).

The dmft found in these children was 0.55 with a standard deviation of 1.088 and the DMFT was 0.733 with a standard deviation of 1.10. The dmft found in children with perinatal HIV infection was low and was marginally significant (p=0.072, p > 0.05 however p < 0.10,) compared with that of normal children. However no significant differences were found in DMFT of these children when compared with that of normal children (p= 0.238) (Table.4).

DISCUSSION
Oral health care is an important component of all round care for people with HIV infection (19). The lack of healthy, functioning dentition can adversely affect the quality of life, complicate the management of medical conditions, and create or exacerbate nutritional and psychosocial problems (20). Some anti-retroviral drugs are sucrose based in the form of a syrup or suspension, such as Zidovudine, and others may lead to decreased salivation, which makes them potentially cariogenic (21).

In South Africa an oral examination was performed on 87 HIV positive children ranged between 3.2 and 7yrs, who were not receiving antiretroviral treatment. Rampant caries early in childhood was found in 19 (21.8%) children, with 5 children suffering severe pain from multiple carious teeth (22). The study in Romanian population consisted of 173 children at age range 6 to 12 years noted severe dental caries in the majority of children (dmfs/dmft 16.9/3.7 and DMFS/DMFT 8.1/3.1) (23).

According to Howell et al (24). The prevalence of caries in HIV children was very high, especially with deciduous dentition. Tofsky et al.(25) found a mean dmft average of 8.3 for children with HIV, while for children not infected with HIV this average was 3.1 teeth, which showed, according to the authors, the need of guidance and treatment for...
those infected patients. A comparative study of the prevalence of caries, by Souza et al (26). In HIV infected children and children without evidence of immunosuppression, showed statistically significant difference between the average mean dmft (5.29; 2.59) and DMFT (2.36; 0.74) of the two groups, respectively. Other recent studies showed that the high prevalence of caries in infected children seems to be greater in those that are in advanced stage of disease and with more severe degree of immunosuppression (27).

Poorandokht et al., found that 54 children of the 100 children examined had rampant caries and rampant caries was the most common oral manifestations of AIDS in those children (54%) followed by periodontal disease (44%), further authors suggested that Rampant caries and severe periodontal diseases (mean CD4 count, 523±297) might have caused tooth loss and dentures use in some patients with severe immunosuppression, resulting in not being categorized as rampant caries (28).

Beena JP et al, found that the primary dentition group had a mean deft of 5.07 ± 5.29 and a caries prevalence of 58.62%; in the mixed dentition group the mean deft was 3.81 ± 3.41 and the mean DMFT was 1.40 ± 2.03 with caries prevalence of 86.20%. In the permanent dentition group the mean DMFT was 3.00 ± 2.37 with a caries prevalence of 76.47% (29).

It was however observed that the prevalence of dental caries recorded in the present study was lower than those previously reported. Dental caries prevalence in these HIV positive children although lower than that seen in other studies was however did not differ significantly when compared to reports of healthy children residing in the same city.

Although the exact reason for the low levels of dental caries prevalence recorded in this study was not apparent, it may be attributable to the general high level of oral health awareness and the diet they consumed which completely eliminated the added sugars, which leads to good oral health and restorative care. (Image 2)

**CONCLUSIONS**

Children with perinatal HIV infection who stayed at Calvary chapel home of hope had a favorable dental behavior and the caries experience was low.

**IMPORTANCE OF THIS PAPER**

Survival rates for children born with HIV who receive antiretroviral therapy are more than double those for children who do not. However Some anti-retroviral drugs are sucrose based in the form of a syrup or suspension, such as Zidovudine, and others may lead to decreased salivation, which makes them potentially cariogenic.

Many recent studies have demonstrated high caries prevalence rates in these children; however in the present study we found a group of children taking ART with low prevalence of caries.
